1 Introduction

In numerous application fields, there is an increasing need to analyze topological and geometric information about shapes. Given a real-valued function on a topological space, only commonly used object for such analysis is the Reeb graph, which encodes the changing component structure of the level sets of the object. The resulting graph also inherits a real-valued function from this setup. Reeb graphs are utilized in a variety of computational topology and topological data analysis applications in order to get a lower dimension representation of a structure which maintains topological properties of the original data, such as shape analysis [30, 36], data skeletonization [14, 34], and surface denoising [55]. **[Josh: We could cite some use cases from vis, sgp, meshing, etc. literature here rather than in paragraph 3.]**

The Reeb graph is constructed on a data set known as an \mathbb{R} -space, which is an assignment of scalar data to each point of a topological space. More formally, we say an \mathbb{R} -space is a pair (\mathbb{X}, f) , where \mathbb{X} is a topological space and $f : \mathbb{X} \rightarrow \mathbb{R}$ is a continuous, scalar valued function. In physics and other applied settings, \mathbb{R} -spaces are more commonly referred to as *scalar fields*. While the definitions of these two objects are identical, we often think of scalar fields having some additional structure on the space, such as being a simply connected domain. In particular, many common physical phenomena, such as temperature of a surface or distribution of pressure in a liquid, can be described using scalar fields.

As Reeb graphs have become more popular for visualisation, analysis, and comparison of such data sets, there has been an increase in interest in defining distances between Reeb graphs or scalar fields; these ideas can also be expanded and modified to many other cases where we have a graph with some form of function defined on

it representing the data, such as mapper graphs [15, 22, 23, 25, 37, 45, 50], merge trees/dendrograms [32, 51], contour trees [12], and Morse-Smale complexes [27, 28]. Not only is this interest sparked by mathematical intrigue, but measuring similarity in these topological structures has shown useful when comparing multiple scalar fields together [46, 47, 52].

Researchers have pulled from various areas of mathematical research such as Banach and metrics spaces, category theory, sequence and string matching, and graph theory [CITE THESE?] in order to provide inspiration for distances that we can define on Reeb graphs. There are (at least) three different distances which have been defined on Reeb graphs which the literature has shown to be promising: the interleaving distance [49], the functional distortion distance [2], and the Reeb graph edit distance [24]. [Erin: should we add more citations, or just the first paper of each distance here?] Each distance has been shown to be both stable and be more discriminative than the well-studied bottleneck distance [CITE BOTTLENECK DISTANCE], leading us to believe that these metrics can be useful in the application sense.

Unfortunately, with the varying fields that these metrics have been pulled from, it is not always immediately clear how these metrics relate to one another or which may work better on certain types of data. Several papers have proven bounds comparing the distances [Bauer2020, 2], yet there is a lack of a cohesive story for the landscape of these distances. Furthermore, while each metric has been heavily researched in recent years, the computational difficulties and overall complexity of these metrics have introduced challenges for both the applied researcher intending to compute these distances, as well as the newcomer who is attempting to develop an intuition for how these metrics operate. [Josh: I think we’re leading the reader to a problem without stating it. What is the “need” for this survey?]

Our contribution This work is a constructive survey focusing on the three aforementioned distances, as well as an analysis of the properties of each metric so that we can better understand the relationship and use cases for each. Furthermore, this paper will

- provide concrete examples for these distances to help develop the intuition of new researchers;
- provide returning researchers a reference for fundamental properties of each metric;
- compare and contrast the various metrics and introduce a common nomenclature for their properties in general;
- provide guidelines for which applied scenarios each metric would be well-suited;
- discuss the computational hurdles and the literature of possible approximations and/or simpler cases for each metric (merge tree, contour tree, etc.).

[Josh: The above feels more like “symptoms” of the high level problem/challenge this work is addressing.] [Josh: “intend to x” is leaving it to the reader to decide whether or not we deliver]

1.1 Notation Considerations

[Brian: We should distinguish between abstract, combinatorial, geometric, and topological Reeb graph. Abstract refers to the Reeb cosheaf, combinatorial refers to the Reeb graph as simply a graph with a labeling on the vertices, topological Reeb graph is the Reeb graph viewed as a scalar field/R-space, geometric Reeb graph is the embedding of the topological Reeb graph into \mathbb{R}^n .]

- \mathbb{X} generally refers to a compact 2-manifold (surface), unless otherwise noted as being just a topological space
- (\mathbb{X}, f) is an \mathbb{R} -space / scalar field
- \mathcal{R}_f is the topological Reeb graph of (\mathbb{X}, f) (maybe change back to $\mathcal{R}(f)$).
- F is the abstract Reeb graph / Reeb cosheaf of (\mathbb{X}, f)
- Γ_f is the combinatorial Reeb graph of (\mathbb{X}, f) (the Reeb graph viewed as a labeled multigraph).

2 Basic Definitions

2.1 Scalar Fields and Reeb Graphs

Definition 2.1. A **scalar field** (equivalently an **\mathbb{R} -space**) is a pair (\mathbb{X}, f) where \mathbb{X} is topological space and $f : \mathbb{X} \rightarrow \mathbb{R}$ is a continuous real-valued function.

Definition 2.2. We define an equivalence relation \sim_f on \mathbb{X} by stating that $x \sim_f y$ if $f(x) = f(y) = a$ and x and y both lie in the same connected component of the levelset $f^{-1}(a)$. We define \mathbb{X}_f to be the quotient space \mathbb{X} / \sim_f and define $\tilde{f} : \mathbb{X}_f \rightarrow \mathbb{R}$ to be the restriction of f to the domain \mathbb{X}_f . The pair $\mathcal{R}_f := (\mathbb{X}_f, \tilde{f})$ is called the **Reeb Graph** of (\mathbb{X}, f) .

Without sufficient restrictions on the space \mathbb{X} , it is possible to have Reeb graphs which are not well-behaved. For example, if \mathbb{X} is the unit disk minus the origin and $f(x, y) = y$, the resulting Reeb graph will be non-hausdorff. We say that a scalar field is **constructible** if there are a finite number of critical points of \mathbb{X} and there is a cylindrical structure between the critical points. This guarantees that the Reeb graph \mathcal{R}_f is indeed a graph. Examples of constructible scalar fields/ \mathbb{R} -spaces include piecewise linear functions defined on compact polyhedra and Morse functions defined on compact manifolds. See [49] for a more in-depth treatment of this idea.

In an applied setting, it is common for our topological space to be some compact 2-manifold. Thus, in this document we will further restrict our treatment of these structures to Morse functions defined on compact 2-manifolds (or surfaces). Using Simulation of Simplicity [29], we can often guarantee that our function will be Morse for computational purposes.

The nodes of the Reeb graph have a well-defined structure to them: a degree 1 node with one edge exiting the node corresponds to an index 0 or minima of the scalar field; a degree 1 node with one edge entering the node corresponds to an index 2 or maxima of the scalar field; a degree 3 node corresponds to a index 1 or saddle point of the scalar field. Saddle points which have two edges entering the node are called **down-forks** and saddle points which have two edges exiting the node are called **up-forks**.

Remark 2.3. Since the Reeb graph is unique, defining a distance on the Reeb graph is equivalent to stating that we have defined a distance between the scalar fields themselves. We will define these distances in terms of the Reeb graphs of the scalar field while keeping this equivalency in mind. Unless otherwise noted, we assume that two Reeb graphs $\mathcal{R}_f, \mathcal{R}_g$ are defined on possibly different topological spaces \mathbb{X}, \mathbb{Y} .

[Erin: Probably need constructible \mathbb{R} -space to promise that the Reeb graph as defined above is, in fact, a graph.][Brian: Fixed 01-25-21]

[Liz: My favorite example: make \mathbb{X} a disk minus the origin, and take the height function as y value to get a non-Hausdorff Reeb graph.][Brian: Fixed 01-25-21]

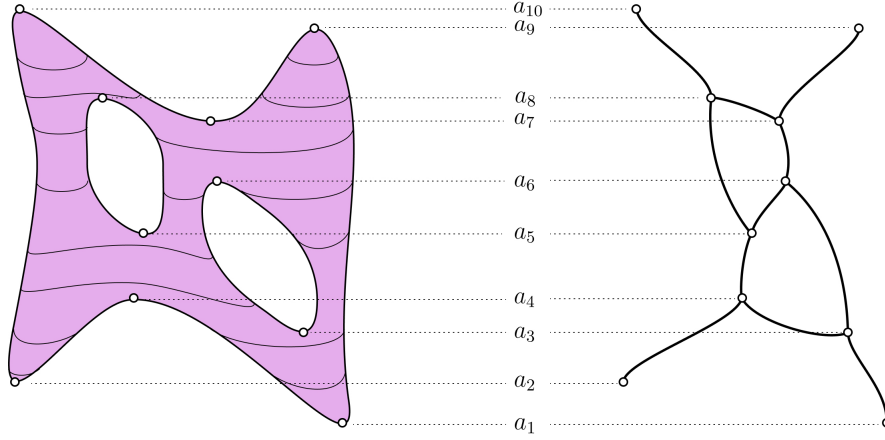

Figure 1: A scalar field (\mathbb{X}, f) , where \mathbb{X} is a 2-manifold and f is a Morse function, along with its corresponding Reeb graph \mathcal{R}_f .

2.2 Stability

Definition 2.4. Let $f, g : \mathbb{X} \rightarrow \mathbb{R}$ be two real-valued continuous functions defined on the same domain. The L^∞ **distance** between f and g is defined as

$$\|f - g\|_\infty := \max_{x \in \mathbb{X}} |f(x) - g(x)|.$$

If d is a metric between the two Reeb graphs $\mathcal{R}_f, \mathcal{R}_g$, we say that d is **stable** if

$$d(\mathcal{R}_f, \mathcal{R}_g) \leq \|f - g\|_\infty$$

Stability helps us ensure that these metrics do not compute arbitrarily large values for two Reeb graphs defined on the same domain. However, each of these metrics can be defined on two Reeb graphs that differ in both function *and* the topological space on which they are defined. A metric that is stable does not state any conclusion about these cases.

2.3 Extended Persistence

Persistence intuitively captures the length of time that features of a scalar field (or other data sets [CITE]) take to disappear once they have been introduced. The notion of persistence has been widely used as a tool in topological data analysis [CITE]. The data provided by persistence can be compactly encoded into a **barcode**—where each feature is provided is associated with a horizontal bar corresponding to the length of time that the feature exists in the data—or in a **persistence diagram**—where each feature is a coordinate pair (a, b) with a representing the birth time and b representing the death time.

While a Reeb graph provides a finer grained detail of the topology of a scalar field, the persistence diagram has been proven useful for its computability and the slew of metrics that can be defined on these persistence diagrams which are also computationally tractable [CITE]. We refer the reader to [26] for a more detailed overview of persistence diagrams and metrics defined on these diagrams.

2.3.1 Definition

Let (\mathbb{X}, f) be a scalar field with critical points $\{v_1, \dots, v_k\}$. We define $\mathbb{X}_a := f^{-1}(-\infty, a]$ to be **sublevel set** of \mathbb{X} at a . Now, let $\{b_0, \dots, b_k\}$ be a set of real numbers such that

$$b_0 < f(v_1) < b_1 < f(v_2) < \dots < b_{k-1} < f(v_k) < b_k.$$

This induces a sequence of nested subspaces

$$\emptyset = \mathbb{X}_{b_0} \subset \mathbb{X}_{b_1} \subset \dots \subset \mathbb{X}_{b_{k-1}} \subset \mathbb{X}_{b_k} = \mathbb{X},$$

called a **filtration** of the scalar field (\mathbb{X}, f) . We can then associate each \mathbb{X}_{b_i} with a corresponding homology group $H_n(\mathbb{X}_{b_i})$ for a fixed dimension n to obtain the sequence

$$\emptyset = H_d(\mathbb{X}_{b_0}) \rightarrow H_d(\mathbb{X}_{b_1}) \rightarrow \dots \rightarrow H_d(\mathbb{X}_{b_{k-1}}) \rightarrow H_d(\mathbb{X}_{b_k}),$$

where each arrow between homology group represents the homomorphism $h_d^{i,j} : H_d(\mathbb{X}_{b_i}) \rightarrow H_d(\mathbb{X}_{b_j})$ induced by the inclusion $\mathbb{X}_{b_i} \subset \mathbb{X}_{b_j}$. Note that we have chosen these $\{b_0, \dots, b_k\}$ to be specifically interleaved between the critical values of f so that the homology of the sequence changes at every iteration ¹.

Definition 2.5. The **d^{th} -persistent homology groups** are the images of the homology group homomorphisms, $H_d^{i,j} := \text{Im}(h_d^{i,j})$ and the **d^{th} -persistent Betti numbers** are their corresponding ranks, $\beta_d^{i,j} = \text{Rank}(H_d^{i,j})$.

The classes of homology groups intuitively represent various n -dimensional holes in the surface. Classes of H_0 represent connected components and classes of H_1 represent closed loops. The Betti numbers corresponding to a particular topological space then simply count the number of holes. Thus, the 0^{th} Betti numbers tell us the number of connected components, while the 1^{st} Betti numbers tell us the number of loops, and so on.

Definition 2.6. We say that a class α is **born** at i if $\alpha \in H_d(\mathbb{X}^i) - \text{Im}(h_d^{i-1,i})$. We say that α **dies** at j if $h_d^{i,j-1}(\alpha) \notin \text{Im}(h_d^{i-1,j-1}(\alpha))$ but $h_d^{i,j}(\alpha) \in \text{Im}(h_d^{i-1,j}(\alpha))$. The **persistence** of α is $f(v_j) - f(v_i)$. If α never dies, then we say that the persistence of α is $+\infty$.

Low persistence features are often attributed to *noise* or *unimportant* features of the data being studied, while high persistence features are often associated with *important* features.

Definition 2.7. The **d^{th} -persistence diagram** of f , denoted as $\text{Dgm}_d(f)$, is a visualization of its persistent features that records each feature α of the d^{th} -persistent homology groups as a coordinate pair $(f(v_i), f(v_j))$, where α is born in \mathbb{X}_i and dies entering \mathbb{X}_j , in the extended plane $\mathbb{R}^2 := \mathbb{R} \cup \{+\infty\} \times \mathbb{R} \cup \{+\infty\}$.

If the class α is born at \mathbb{X}_i and never dies, it is represented as the coordinate $(f(v_i), +\infty)$ in the persistence diagram. Such classes are known as **essential** homology classes. The ordered pairs of a persistence diagram correspond directly to pairs of critical points in a scalar field, which in turn correspond to nodes in the Reeb graph. Index 0 critical points create connected components (0-dimensional homology classes) which are then destroyed by down-forks while up forks create closed loops (1-dimensional homology classes) which are destroyed by index 2 critical points. However, critical points which create essential homology classes are not paired with other critical points in the scalar field like inessential homology classes are. To alleviate this, we can leverage Poincare and Lefschetz duality to create a new sequence of homology groups where we

¹The homology groups do not necessarily change, but the only possible places that these sublevelsets have different topologies is when we pass over critical points. Choosing values that are not surrounding the critical points would cause our sequence to have multiple homology groups that are guaranteed to be repeated.

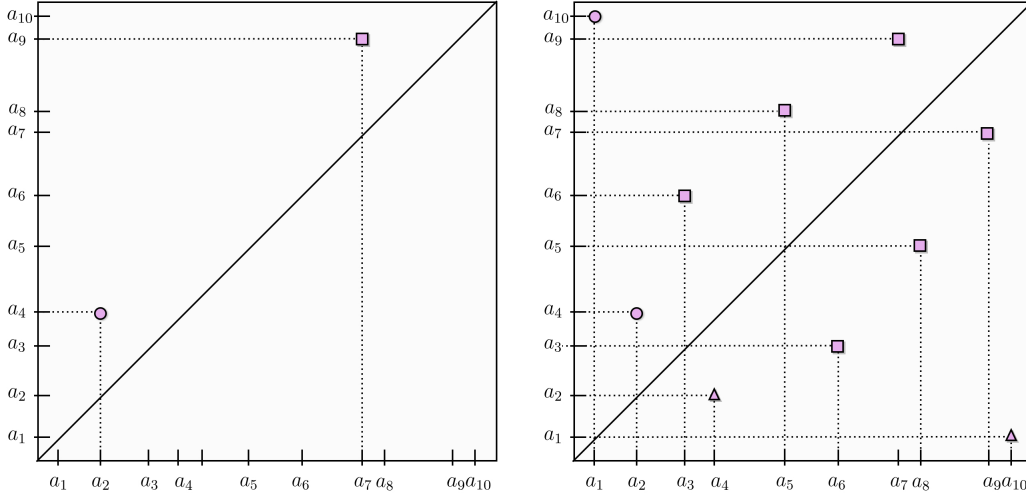

Figure 2: The ordinary persistence and extended persistence diagrams for the surface in Figure 1. Circles denote H_0 classes, squares denote H_1 classes, and triangles denote H_2 classes.

begin and end with the trivial group [16]. This guarantees that each homology class that is born will also die, meaning each critical point in the Reeb graph will be matched with another critical point at least once.

Let $X^a := f^{-1}[a, \infty)$ be the **superlevel set** of \mathbb{X} at a and let $H_k(\mathbb{X}, \mathbb{X}^a)$ denote the relative homology group. From this, we can create a new sequence of homology groups

$$\begin{aligned} 0 = H_d(\mathbb{X}_{b_0}) &\rightarrow H_d(\mathbb{X}_{b_1}) \rightarrow \dots \rightarrow H_d(\mathbb{X}_{b_{i-1}}) \rightarrow H_d(\mathbb{X}_{b_i}) \\ &= H_d(\mathbb{X}, \mathbb{X}^{b_i}) \rightarrow H_d(\mathbb{X}, \mathbb{X}^{b_{i-1}}) \rightarrow \dots \rightarrow H_d(\mathbb{X}, \mathbb{X}^{b_1}) \rightarrow H_d(\mathbb{X}, \mathbb{X}^{b_0}) = 0. \end{aligned}$$

We can now construct an **extended persistence** diagram, denoted $\text{ExDgm}_d(f)$, from the new pairs in the same fashion as before. To differ between the two types persistence, we will often use the term **ordinary persistence** for the former process. However, we should note that extended persistence is strictly more powerful than ordinary persistence because it captures all inessential homology classes as well as essential homology classes, where as ordinary persistence will only capture inessential classes.

Preliminary results in [1] showed a pairing between all critical points of a 2-manifold while [16] extended this to general manifolds later. We provide a standard example of extended persistence and the process behind it to give the reader some intuition.

Example 2.8. Figure 1 shows a genus-2 surface embedded in \mathbb{R}^3 along with its Reeb graph. To find the persistence pairs, we begin by sweeping upwards and tracking the features which are born and destroyed. Critical points a_1 and a_2 create classes in H_0 ; a_3, a_5, a_6, a_7 , and a_8 create classes in H_1 ; a_{10} creates a class in H_2 . We pair a_2 with a_4 since a_4 merges two connected components together, and we pair a_7 with a_9 since a_9 closes a hole created by a_7 . Thus, the ordinary persistence diagram contains only two points. Going downwards, a_{10} destroys the class in H_0 created by a_1 ; a_6, a_8, a_3 and a_5 destroy the classes in H_1 created by a_3, a_5, a_6 and a_8 , respectively; a_{10} and a_4 create classes in H_2 which are destroyed by a_1 and a_2 , respectively. Thus, we have the pairs (a_1, a_{10}) and (a_4, a_2) for dimension 0; $(a_3, a_6), (a_5, a_8), (a_6, a_3)$ and (a_8, a_5) for dimension 1; (a_4, a_2) and (a_{10}, a_1) for dimension 2. Figure 2 shows the ordinary and extended persistence diagrams for this example.

Remark 2.9. [Brian: Remark about not using zigzag persistence]

2.3.2 Bottleneck Distance

[Brian: Need history of bottleneck distance?]

Definition 2.10. Let $(\mathbb{X}, f), (\mathbb{Y}, g)$ be two scalar fields and $F := \text{ExDgm}_d(f), G := \text{ExDgm}_d(g)$ be the their corresponding extended persistence diagrams. We define the bottleneck distance d_B between these diagrams as

$$d_B(F, G) = \inf_{\eta: F \rightarrow G} \sup_{x \in F} \|x - \eta(x)\|_\infty,$$

where η is a bijection between F, G .

Remark 2.11. For purposes of finding the bottleneck distance, we add infinitely many points to the diagonal of the persistence diagram. This allows the bijection to pair an off-diagonal point to the diagonal.

Theorem 2.12. Let $(\mathbb{X}, f), (\mathbb{X}, g)$ be two constructible scalar fields² defined on \mathbb{X} . Then

$$d_B(\text{ExDgm}_d(f), \text{ExDgm}_d(g)) \leq \|f - g\|_\infty.$$

That is, the bottleneck distance is a stable metric.

[Brian: Need Example]

[Brian: Definition of Wasserstein distance?]

3 Interleaving Distance

3.1 History

[Liz: This is direct self-plagarism and requires editing] [Erin: Took a stab at this on 1/29 - please re-check for coherence] The interleaving distance on Reeb graphs takes root in earlier work that defines the interleaving distance for persistence modules [13], and is heavily inspired by the subsequent category theoretic treatment [9, 10]. This viewpoint comes from encoding the data of a Reeb graph in a constructible set-valued cosheaf [18–20]. In fact, it is known that this metric is a special case of a more general theory of interleaving distances given on a *category with a flow* [17, 21, 53]; this more general theory also encompasses other metrics including ℓ_∞ distance on points or functions, regular Hausdorff distance, and the Gromov-Hausdorff distance [11, 53].

Interleaving metrics have been studied in the context of \mathbb{R} -spaces [6], multiparameter persistence modules [40], merge trees [42], and formigrams [38, 39], and on more general category theoretic constructions [7, 48], as well as developed for Reeb graphs [49] [Erin: Add link to our newer paper for truncated smoothing once we have it]. There are also interesting restrictions to labeled merge trees, where one can pass to a matrix representation and show that the interleaving distance is equivalent to the point-wise ℓ_∞ distance [33, 43, 54, 56].

On the negative side, it has been shown that Reeb graph interleaving is graph isomorphism complete [4, 49], and that many other variants are also NP-hard [4, 5]. All of this means that these metrics, while mathematically interesting, may not lead to feasible algorithms for comparison and analysis. However, a glimmer of hope arises with work investigating fixed parameter tractable algorithms [31, 54], and comparisons

²We can show this result for two tame functions f, g defined on the same simplicial complex. Constructibility is more a more restrictive property than tame functions.

are possible in polynomial time if the Reeb graph has simple enough structure, such as a contour tree or merge tree.

In addition, notions of similarity for graphs in general, and Reeb graphs in particular, are of pressing interest due to their extensive use in data analysis; in many such settings, we are concerned with questions of quality in the face of noise, and computing approximations to the exact object with may converge nicely in some abstract limit. For example, the interleaving distance has been used in evaluating the quality of the mapper graph [50], which can be proven to be a approximation of the Reeb graph using this metric [8, 44]. Furthermore, there is considerable interest in unifying the interleaving distance with the emerging collection of other Reeb graph metrics.

3.2 Definition

A **pre-cosheaf** is a functor F from the category of intervals on the real line \mathbf{Int} to the category of sets \mathbf{Set} ³. Intuitively, it is a way to assign data to the open intervals of the real line in a way that respects inclusion of the intervals. Given a Reeb graph \mathcal{R}_f we can construct its pre-cosheaf F by the formulas

$$F(I) = \pi_0(f^{-1}(I)), \quad F[I \subseteq J] = \pi_0[f^{-1}(I) \subseteq f^{-1}(J)],$$

where $\pi_0(U)$ is the set of path connected components of the set U . Stating that two Reeb graphs $R(f), R(g)$ are isomorphic is equivalent to stating that their associated pre-cosheafs F, G are isomorphic. Recall that an isomorphism between two functors is a pair of natural transformations $\varphi : F \Rightarrow G, \psi : G \Rightarrow F$ such that $\psi_I \circ \varphi_I = \mathbf{Id}_{F(I)}$ and $\varphi_I \circ \psi_I = \mathbf{Id}_{G(I)}$, for all $I \in \mathbf{Int}$. If we do not have a true isomorphism between these pre-cosheafs, we can approximate the isomorphisms to form an ε -**interleaving**.

Remark 3.1. *[Brian: Statement about how Reeb graphs actually form cosheafs (rather than just pre-cosheafs). Then we can just use the term cosheaf for the rest of the section.]*

Definition 3.2. Let $I = (a, b) \subseteq \mathbb{R}$ and $I^\varepsilon = (a - \varepsilon, b + \varepsilon)$. The ε -**smoothing functor**, $\mathcal{S}_\varepsilon : \mathbf{Pre} \rightarrow \mathbf{Pre}$, where $\varepsilon > 0$, is defined by $\mathcal{S}_\varepsilon(F(I)) = F(I^\varepsilon)$ for each I .

In essence, the ε -smoothing functor expands each interval I by ε in both directions before assigning data. This implies that the minimum width of an interval is now 2ε rather than a single point. In several cases, the increase in the intervals causes the data associated to these intervals to be fundamentally changed, sometimes removing features entirely. Figure 4 shows two examples of smoothing for various simple features. Note that while the smoothing operation is done on the cosheafs directly, we can represent this using the Reeb graph since the fundamental structure of the cosheaf is captured completely in the Reeb graph, as seen in 3.

Definition 3.3. Let σ_F^ε be the natural transformation $F \Rightarrow \mathcal{S}_\varepsilon(F)$ created by noting that $I \subseteq I^\varepsilon$ implies $F(I) \rightarrow F(I^\varepsilon) = \mathcal{S}_\varepsilon(F)$. We say that two cosheafs F, G are ε -**interleaved** if there exists a pair of natural transformations $\varphi : F \Rightarrow \mathcal{S}_\varepsilon(G)$ and $\psi : G \Rightarrow \mathcal{S}_\varepsilon(F)$ such that the following diagrams commute:

³In general, we can define pre-cosheafs where the domain category is the open sets of any topological space and the range category is unrestricted.

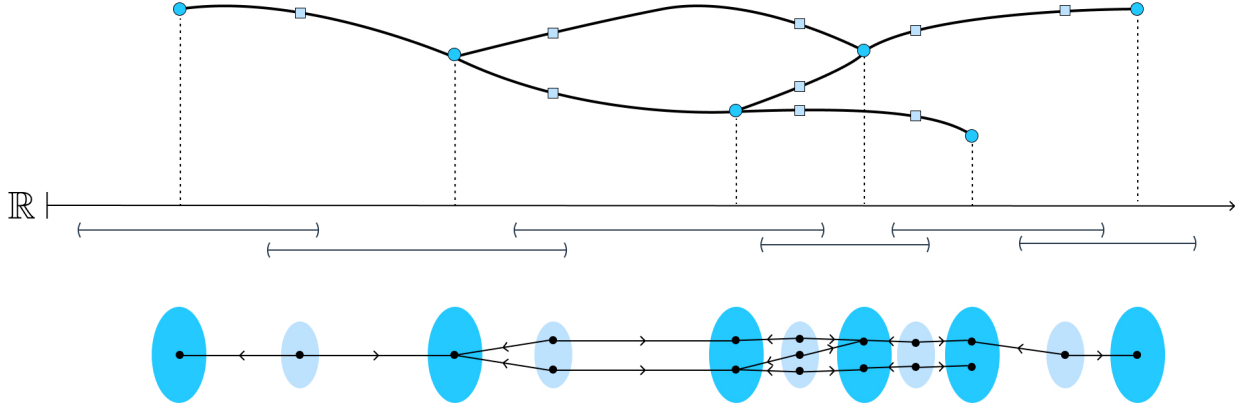

Figure 3: A Reeb graph (Top) with its corresponding cosheaf (bottom). The larger, darker blue sets were chosen specifically to surround the critical points of the Reeb graph. The smaller, light blue sets are the pairwise intersection of the sets surrounding it. The arrows represent the morphisms from each small set to the larger sets they are included in. While a cosheaf is defined for *all* intervals on the real line, the intervals above are enough to capture the topology of the Reeb graph fully. This figure was adapted from [49].

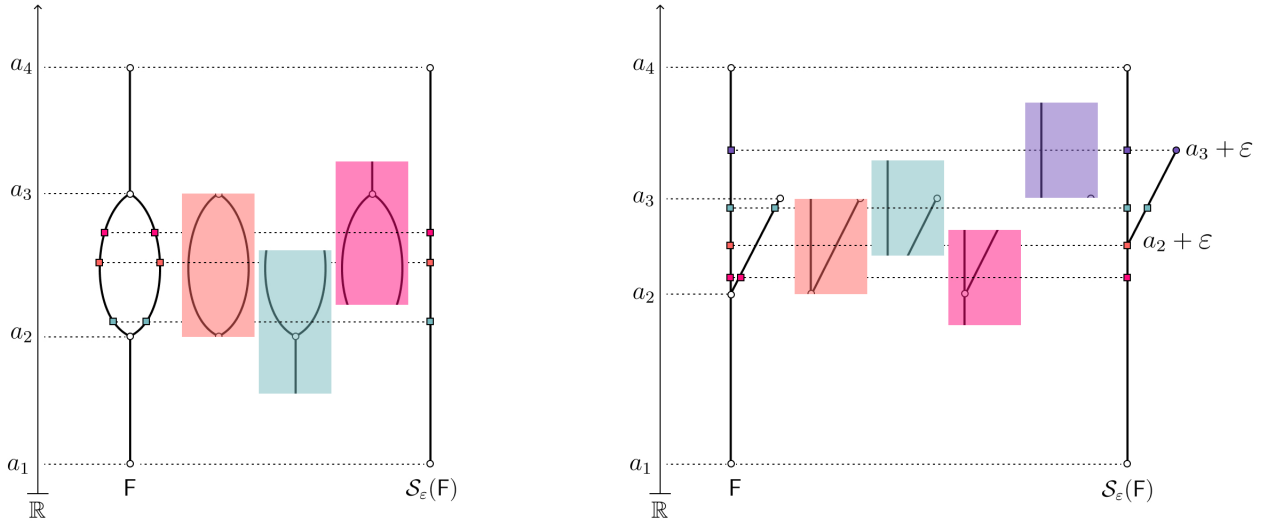

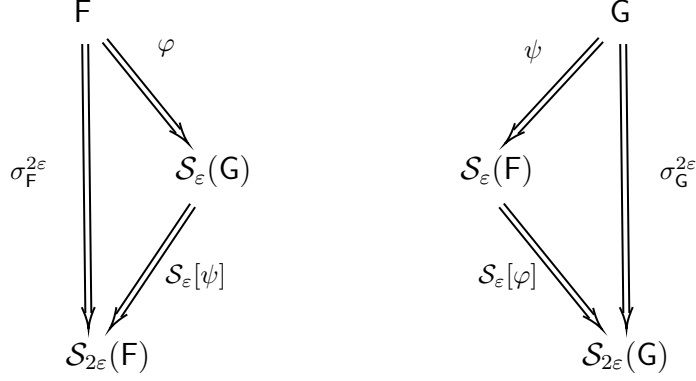

Figure 4: (Left) A Reeb graph of a torus along with its ε -smoothed version. To cover the hole completely, ε has to be large enough so that every interval I , the expanded interval I^ε will only have one path connected component. Setting $\varepsilon \geq \frac{a_3 - a_2}{2}$ will guarantee this. (Right) Leaves of a Reeb graph will be shifted by ε . As the center of the interval passes $\frac{a_3 + a_2}{2}$, the number of components changes from one to two, essentially creating a leaf in the smoothed version that is shifted upwards. Note that the last component (purple) maps to only *one* component in the smoothed Reeb graph. Similarly, a leaf pointing downwards will be shifted downwards by ε .

If $\varepsilon = 0$, then this is exactly the definition of an isomorphism between F and G . When two cosheafs are ε -interleaved, we say that there exists an ε -**interleaving** between them.

Definition 3.4. *The interleaving distance between two Reeb graphs $\mathcal{R}_f, \mathcal{R}_g$ is the minimum ε such that their respective cosheafs are ε -interleaved. Formally,*

$$d_I(\mathcal{R}_f, \mathcal{R}_g) = \inf_{\varepsilon \in \mathbb{R}^+} \{ \varepsilon \mid \text{there exists an } \varepsilon\text{-interleaving between } F \text{ and } G \},$$

where F, G are their respective cosheafs.

3.3 Properties and Examples

[Brian: ***This is basically implied for stability when we are defined on the same manifold***
For properties, I think we can define a property which refers to "worst-case" scenario. Suppose \mathbb{X} is the surface of a torus, f is the height function (where the torus is on its side like usual) and $g(x) = f(x + \delta_x)$, where $\delta_x > 0$ is a small, random positive number (some noise). The interleaving distance between (\mathbb{X}, f) and (\mathbb{X}, g) would simply be the maximum δ_x , instead of summing all the differences in noise. FDD shares this same property.]

Several nice properties are immediate when using the interleaving distance, as well as some drawbacks or cases where it is not useful.

Proposition 3.5 (Proposition 4.3 in [49]). *The interleaving distance d_I is an extended pseudometric: it takes values in $[0, \infty]$, is symmetric, satisfies the triangle inequality, and $d_I(F, F) = 0$.*

[Erin: Need some transition text here to translate and contextualize the next few theorems, I think]

Theorem 3.6 (Theorem 4.4 in [49]). *Let \mathcal{R}_f and \mathcal{R}_g be two Reeb graphs defined on the same space \mathbb{X} , and let F, G be their respective cosheafs. Then*

$$d_I(\mathcal{R}_f, \mathcal{R}_g) \leq \|f - g\|_\infty$$

Proposition 3.7 (Proposition 4.5 in [49]). *The interleaving distance between two Reeb graphs is finite if and only if they have the same number of path components.*

Proposition 3.8 (Proposition 4.6 in [49]). *The interleaving distance between two Reeb graphs is zero if and only if they are isomorphic.*

- Interleaving distance is NOT invariant to shift in function value, i.e. if $g(x) = f(x) + \delta$, for some $\delta > 0$, then the interleaving distance between the Reeb graphs of (\mathbb{X}, f) and (\mathbb{X}, g) is at least δ (might be exactly delta)
- Let U be an open subset of \mathbb{X} such that \mathbb{X} has a maximum in U . Suppose $f_1 = f_2$ except on U , where $f_1 > f_2$ and is interpolated to the boundary of U so that both functions are still continuous. We can picture this as two identical functions except where one maximum is larger than the maximum located at the same subset of \mathbb{X} . The interleaving distance is equal to the distance in the maximum's function value.
- The interleaving distance between a single loop Reeb graph and a single line Reeb graph (assuming that the minimum function value and maximum function value is equal) is $\varepsilon = \delta/2$, where δ is half the distance between the bottom and top of the loop.
- The interleaving distance between a single leaf Reeb graph and a single line Reeb graph (assuming that the minimum function value and maximum function value is equal) is $\varepsilon = \delta/2$, where δ is half the distance between the bottom and top of the leaf.

Use Cases

- Possibly good for time-dependent scalar fields, such as feature tracking over time. Small changes in the features of a scalar field should lead to relatively low interleaving distance
- NOT good for multimodel simulations where we compare various types of data. The difference in scale will certainly cause large interleaving distances

4 Functional Distortion Distance

4.1 History

[Brian: I might be wrong on some of these facts, so should double check.]

The functional distortion distance was first defined as a metric in [2], inspired from the well-known Gromov-Hausdorff distance which was first introduced in [35]. The Gromov-Hausdorff distance is a way to measure the distance between two Banach or metric spaces. More formally, suppose A and B are two metric spaces and let $i_A : A \rightarrow Z, i_B : B \rightarrow Z$ be isometric embeddings into a common metric space Z . We can then find the Hausdorff distance between the embeddings: $d_H(i_A(A), i_B(B))$. [Erin: Just adding a note as I'm reading - have we formally defined Hausdorff distance somewhere?]

The goal of the functional distortion distance is then to find the minimum Hausdorff distance achieved by ranging over all possible embeddings and the common space to which they are embedded. Intuitively, we are trying to determine a common area where we can embed both A and B , while preserving the integrity of the spaces (hence the embeddings being isometries), such that the A and B fit nicely together. We can picture A and B as being two crumpled up pieces of paper (of varying sizes) and our common metric space to be a flat surface. One way to measure the difference in sizes between A and B is to stretch both out flat onto the surface and then compare them that way. Trying to determine the sizes while the paper is still crumpled would be a much more difficult task.

4.2 Definition

[Brian: 01/29/20] The Gromov-Hausdorff distance has multiple different equivalent definitions; see [41]. Functional distortion distance borrows from a very specific variation of the GH distance.

Definition 4.1. Let $u, v \in \mathcal{R}_f$ (not necessarily nodes) and let π be a continuous path between u and v . The **range** of this path is the interval $\text{range}(\pi) = [\min_{x \in \pi} f(x), \max_{x \in \pi} f(x)]$. The **height** is the length of the range, denoted $\text{height}(\pi) = \max_{x \in \pi} f(x) - \min_{x \in \pi} f(x)$. We define the distance between u and v to be

$$d_f(u, v) = \min_{\pi: u \rightsquigarrow v} \text{height}(\pi),$$

where π ranges over all continuous paths from u to v , denoted $u \rightsquigarrow v$, and f in d_f refers to the function f .

Definition 4.2. Let $\varphi : \mathcal{R}_f \rightarrow \mathcal{R}_g$, $\psi : \mathcal{R}_f \rightarrow \mathcal{R}_g$ be two continuous maps.⁴ We define the **supergraph** of φ and ψ as

$$G(\varphi, \psi) = \{(x, \varphi(x)) : x \in \mathcal{R}_f\} \cup \{(\psi(y), y) : y \in \mathcal{R}_g\}.$$

$G(\varphi, \psi)$ is simply the union of the two graphs of φ and ψ .

Definition 4.3. The **distortion** λ between $(x, y), (x', y') \in G(\varphi, \psi)$ is defined as

$$\lambda((x, y), (x', y')) = \frac{1}{2} |d_f(x, x') - d_g(y, y')|.$$

We define the distance $D(\varphi, \psi)$ between \mathcal{R}_f and \mathcal{R}_g based on the correspondences φ and ψ to be supremum of distortions ranging over all possible pairs in the supergraph $G(\varphi, \psi)$. That is,

$$D(\varphi, \psi) = \sup_{(x, y), (x', y') \in G(\varphi, \psi)} \lambda((x, y), (x', y')).$$

[Brian: In the original paper, they don't call this distortion. But it seems like a very fitting word. This will also create a better understanding of the difference between this value and the FDD (so FDD is the infimum of all distortions ranging over the continuous maps).] In essence, this distance will measure how much each Reeb graph is being distorted to map into the other Reeb graph. For example, if x and x' are relatively close (in terms of d_f) but their outputs under φ are far apart (in terms of d_g), then this distance will be larger. This distance finds the worst case scenario where two points are close on one Reeb graph and their correspondences are far on the other. Keep in mind that there are two maps φ and ψ . Thus, even if both maps are non-surjective, every point of each Reeb graph still has at least one correspondence in the supergraph $G(\varphi, \psi)$.

Definition 4.4. The **functional distortion distance** is defined as

$$d_{FD}(\mathcal{R}_f, \mathcal{R}_g) = \inf_{\varphi, \psi} \max\{D(\varphi, \psi), \|f - g \circ \varphi\|_\infty, \|f \circ \psi - g\|_\infty\},$$

where φ and ψ range over all continuous maps between \mathcal{R}_f and \mathcal{R}_g .

Remark 4.5. If φ and ψ are simply translations or negations, the distances d_f and d_g are not affected since these will preserve the relative closeness of the pairs (x, x') and (y, y') . In this case, $D(\varphi, \psi)$ would be 0. The two terms $\|f - g \circ \varphi\|_\infty$ and $\|f \circ \psi - g\|_\infty$ are introduced to address this fact. They simply measure the length of the translation or similar isometries. See Figure 6 for an example.

⁴These continuous maps need not be function preserving like in the category of Reeb graphs. In other words, these maps are not well-defined morphisms between \mathcal{R}_f and \mathcal{R}_g as objects in **Reeb**.

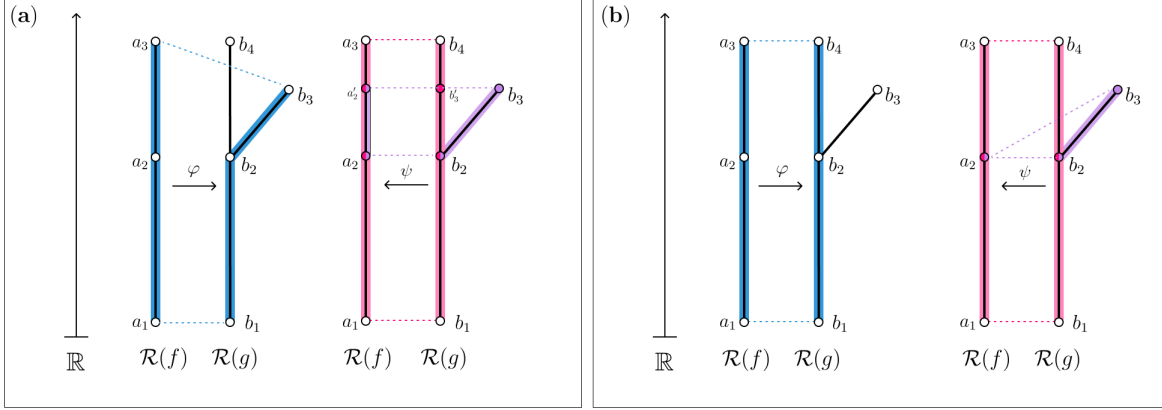

Figure 5: Two examples of continuous maps between simple Reeb graphs \mathcal{R}_f and \mathcal{R}_g as described in example 4.6. Dotted lines indicate the correspondences that these maps are creating, while the color indicates which section we are referring to. (a) The map φ distorts \mathcal{R}_f to fit into the leaf on the right side. The map ψ maps each value straight across. (b) The map φ is an isometry, which will not alter the distortion alone. The distortion will be solely based on ψ , which is almost an isometry except for collapsing the leaf to a single point. It turns out that the map contracting the leaf to a single base point at a_2 will result in an equivalent distortion value to mapping it horizontally as in (a).

Example 4.6. Figure 5 displays two different pairs of continuous maps between \mathcal{R}_f and \mathcal{R}_g . Note that both f and g are height functions which are mapping horizontally to the real line, so we have $f(a_1) = g(a_1)$, etc. In (a), the map φ maps like an isometry up to a_2 , where it then maps the rest of \mathcal{R}_f into the leaf of \mathcal{R}_g . The distortion value between the points (a_3, b_3) and (a_2, b_2) would then be $|d_f(a_3, a_2) - d_g(b_3, b_2)| = f(a_3) - g(b_3)$. For ψ , the map also acts like an isometry, except the leaf is collapsed, mapping horizontally to \mathcal{R}_f . In this case, the supergraph contains the points (a'_2, b'_3) and (a'_2, b_3) . Thus, the distortion between these two points is $|d_f(a'_2, a'_2) - d_g(b'_3, b_3)| = g(b_3) - g(b_2)$. We can check that other pairs of points consisting of pairs from different graphs will not lead to a higher distortion value and that these two distortion values are greatest among possible pairs. Therefore, $D(\varphi, \psi) = \max\{f(a_3) - g(b_3), g(b_3) - g(b_2)\}$. In (b), the map φ is an isometry and therefore no points in the supergraph which come from φ will contribute to the distortion value. The map ψ is close to an isometry besides contracting the leaf to a single point. The distortion value then between the pairs (a_2, b_2) and (a_2, b_3) is simply $g(b_3) - g(b_2)$. Note that this is the same distortion value which was achieved in part (a) when we mapped the leaf straight across to \mathcal{R}_f . This comes from the definition of d_g which only looks at the height of the path that is traversed from one point to the next and does not take into account the total distance traversed.

[Brian: It might be useful to explain why these maps are continuous. Specifically, looking at the image of ψ in (b), the pullback of an open set surrounding the a_2 would contain the whole leaf. Originally, I thought that containment of the whole leaf would surely be a closed set, since it contains the “boundary” node of b_3 . However, when thinking about the topology defined of \mathcal{R}_g , we recall that this is the quotient topology induced by the scalar field. Since we are considering compact 2-manifolds without boundary (general surfaces), we know that the set the entire leaf can be contained in an open set. Specifically, for every point x around the tip of the leaf (the point of interest) there exists a U such that U is still on the manifold (again, since the manifold has no boundary).]

[Brian: I think other works might leave these details to the reader, but I think that’s kind of the point of this, no? Trying to clarify the weird misunderstanding that can come from reading the papers themselves. Also, I don’t think the conclusion is trivial.]

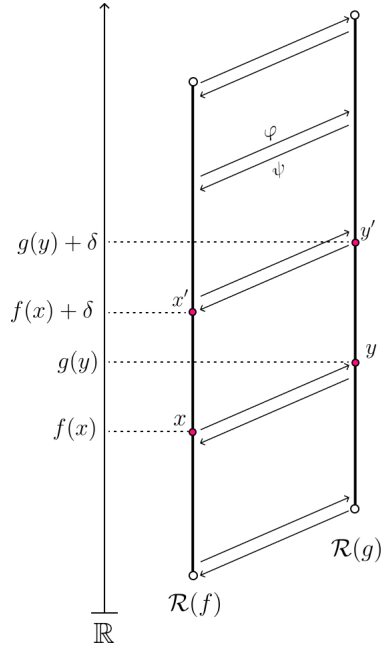

Figure 6: (Left) An example of maps where φ is a translation and $\varphi = \psi^{-1}$. In this, $d_f(x, x') = \delta = d_g(y, y')$, which implies that $D(\varphi, \psi) = 0$. Without the $\|f - g \circ \varphi\|_\infty, \|f \circ \psi - g\|_\infty$ terms, the functional distortion distance between these two Reeb graphs would be 0. With these terms included, we can see that the functional distortion distance will be δ , which is equal to the magnitude of the translation.

[Brian: Can we think of these maps as trying to "fit" these Reeb graphs into one another?]
 [Brian: Similar to interleaving distance, FDD takes worst case scenario as the distance. For example the FDD distance between a height function defined on a torus and the height function with some random, added value to each point (noise), the FDD will simply be the maximum of the noise. This is because once we find how to embedd the noisy torus into the smooth torus, we find the worst pair that is distorted.]

4.3 Properties

5 Edit Distance

5.1 History

5.2 Definition

[Brian: 01/29/20] [Brian: One very important thing to note about the edit distance is that it is totally in the context that both Reeb graphs are defined on the same domain, which is unlike functional distortion distance and interleaving distance. I'm not sure if this necessarily affects the use cases too much, however (why would we compare different domains?). I think the strangest difference is that this means we cannot compare surfaces with holes to those without.]

Let (\mathbb{X}, f) be a scalar field and \mathcal{R}_f be it's Reeb graph. As stated before, (\mathbb{X}, f) being constructible means that our Reeb graph will be a well-defined graph with a finite number of nodes and edges. While functional distortion distance considered \mathcal{R}_f as a topological space and the interleaving distance considered \mathcal{R}_f as a cosheaf \mathbb{F} , here we only need to consider it as a graph, known as the **combinatorial Reeb graph**.

Definition 5.1. A **multigraph** is a graph $\Gamma = (V, E)$, with vertex set V and edge set E , such that the edges in E need not be unique. A **labeled multigraph** is a pair (Γ, l) , where Γ is a multigraph (V, E) and l is a scalar function $l : V(\Gamma) \rightarrow \mathbb{R}$ defined on the vertices of the multigraph.

Definition 5.2. Let (\mathbb{X}, f) be a constructible scalar field and \mathcal{R}_f be its Reeb graph. The **combinatorial Reeb graph**, (Γ_f, l_f) is the labeled multigraph $(V(\Gamma_f), E(\Gamma_f))$, where $V(\Gamma_f)$ and $E(\Gamma_f)$ are the vertices (critical points) and edges of \mathcal{R}_f , respectively, and $l_f = f|_{V(\Gamma_f)}$. That is, the labeling is simply the function f restricted to the vertices of the graph.

5.3 Elementary Deformations

Since the definition of each elementary deformation might seem cumbersome, we accompany each with a diagram to display the operation.

Definition 5.3. T is an elementary deformation of (Γ_f, l_f) of **birth type** if, for a fixed edge $e(v_1, v_2) \in E(\Gamma_f)$, with $l_f(v_1) < l_f(v_2)$, $T(\Gamma_f, l_f)$ is a labeled graph (Γ, l) such that

- (1) $V(\Gamma) = V(\Gamma_f) \cup \{u_1, u_2\}$;
- (2) $E(\Gamma) = (E(\Gamma_f) - \{e(v_1, v_2)\}) \cup \{e(v_1, u_1), e(u_1, u_2), e(u_2, v_2)\}$;

- (3) $l|_{V(\Gamma_f)} = l_f$ and either $l_f(v_1) < l(u_1) < l(u_2) < l_f(v_2)$, with $l^{-1}([l(u_1), l(u_2)]) = \emptyset$ or $l_f(v_1) < l(u_2) < l(u_1) < l_f(v_2)$, with $l^{-1}([l(u_2), l(u_1)]) = \emptyset$.

Definition 5.4. T is an elementary deformation of (Γ_f, l_f) of **death type** if, for fixed edges $e(v_1, u_1), e(u_1, u_2), e(u_1, v_2) \in E(\Gamma_f)$, with u_2 of degree 1 and either $l_f(v_1) < l_f(u_1) < l_f(u_2) < l_f(v_2)$ with $l_f^{-1}([l_f(u_1), l_f(u_2)]) = \emptyset$, or $l_f(v_1) < l_f(u_2) < l_f(u_1) < l_f(v_2)$ with $l_f^{-1}([l_f(u_2), l_f(u_1)]) = \emptyset$, $T(\Gamma_f, l_f)$ is a labeled graph (Γ, l) such that

- (1) $V(\Gamma) = V(\Gamma_f) - \{u_1, u_2\}$
- (2) $E(\Gamma) = (E(\Gamma_f) - \{e(v_1, u_1), e(u_1, u_2), e(u_1, v_2)\}) \cup \{e(v_1, v_2)\}$

5.4 Properties

6 Comparison of Distances

Here, we only consider regular and extended persistence diagrams. I assume that we will try and make it so that all the relationships are in terms of extended persistence (which might not be difficult).

Facts:

1. In [24], we are shown that the Reeb graph edit distance is greater than the functional distortion distance.
2. In [24], we are shown that the Reeb graph Edit distance is greater than the bottleneck distance.
3. In [3], we are shown that the Interleaving Distance and Functional Distortion Distance are strongly equivalent:

$$d_I(f, g) \leq d_{FD}(f, g) \leq 3d_I(f, g)$$

4. In [3] we are shown the relationship between interleaving distance on Reeb graphs compared to the bottleneck distance on persistence diagrams:

$$d_B(\text{Dg}_0(f), \text{Dg}_0(g)) \leq 3d_I(f, g)$$

$$d_B(\text{ExDg}_1(f), \text{ExDg}_1(g)) \leq 9d_I(f, g)$$

5. In [2] we are shown the relationship between functional distortion distance on Reeb graphs and bottleneck distance on persistence Diagrams:

$$d_B(\text{Dg}_0(f), \text{Dg}_0(g)) \leq d_{FD}(f, g)$$

$$d_B(\text{ExDg}_1(f), \text{ExDg}_1(g)) \leq 3d_{FD}(f, g)$$

7 Computation

7.1 Complexity Results

[Brian: Statement of complexity results for each metric, which short discussion. I believe there is a clear difference in the complexity for interleaving distance and functional distortion distance since FDD has to iterate through all continuous maps with less restrictions.]

7.2 Approximations/Implementations

[Brian: Since to our knowledge there are no current approximations/implementations, this section can be more focused on a discussion for pointing research in the right direction. Some points might be the reducing interleaving distance to simpler cases (covering hole example and sliding leaf example)]

8 Alternatives to Reeb Graphs

8.1 Contour Trees

[Brian: Frechet Distance?]

8.2 Merge Trees

[Brian: Current applications are using merge trees or branch decomposition trees of merge tress]

9 Applications

[Brian: Question – If these metrics can be computed/closely approximated, what applications would they be used for?]

[Brian: Question – What other metrics exist for scalar fields that closely resemble these use cases?]
